Prognostic Value of White Blood Cell Count in Acute Myocardial Infarction: Long-Term Mortality

Julio Núñez, Lorenzo Fácil, Ángel Llacer, Juan Sanchís, Vicent Bodí, Vicente Bertomeu, Rafael Sanjuán, María L. Blasco, Luciano Consuegra, María J. Bosch, and Francisco J. Chorro

Servei de Cardiologia, Hospital Clínic i Universitari, Universitat de València, Valencia, Spain. Unidad Coronaria, Hospital Clínic i Universitari, Universitat de València, Valencia, Spain.

Introduction and objectives. Although traditionally an elevated white blood cell count (WBC), an indicator of systemic inflammation, has been accepted as part of the healing response following acute myocardial infarction (AMI), it has frequently been shown to be a predictor of adverse cardiovascular events. The present study was designed to assess the association between WBC and long-term mortality in AMI patients either with ST-segment elevation (STEMI) or without ST-segment elevation (non-STEMI).

Patients and method. The study included 1118 consecutive patients who were admitted with the diagnosis of AMI: 569 non-STEMI and 549 STEMI. The WBC was measured in the 24 hours following admission. Patients were divided into 3 groups: WBC1 (count, <10^9 cells/mL), WBC2 (count, 10-14,9×10^9 cells/mL), and WBC3 (count, ≥15×10^9 cells/mL). All-cause mortality was recorded during a median follow-up period of 10±2 months. The relation between WBC and mortality was assessed by Cox regression analysis for both types of AMI.

Results. Long-term mortality during follow-up was 18.5% in non-STEMI patients and 19.9% in STEMI patients. In non-STEMI patients, the adjusted hazard ratios for those in the WBC3 and WBC2 groups compared with those in the WBC1 group were 2.07 (1.08-3.94; P=.017) and 1.61 (1.03-2.51; P=.036), respectively. The corresponding figures in STEMI patients were 2.07 (1.13-3.76; P=.017) and 2.22 (1.35-3.63; P=.002), respectively.

Conclusions. WBC on admission was an independent predictor of long-term mortality in both non-STEMI and STEMI patients.

Key words: Acute myocardial infarction. Leukocyte count. Mortality.

Valor pronóstico del recuento leucocitario en el infarto agudo de miocardio: mortalidad a largo plazo

Introducción y objetivos. Publicaciones recientes respaldan el papel pronóstico del recuento leucocitario (RL) en pacientes con infarto agudo de miocardio (IAM). El objetivo de este trabajo fue determinar el valor predictivo atribuible al RL, con independencia de otras variables de contrastado valor pronóstico, para predecir mortalidad a largo plazo en pacientes con IAM sin elevación del segmento ST (IAMNEST) y con elevación del segmento ST (IAMEST).

Pacientes y método. Analizamos a 1.118 pacientes admitidos de forma consecutiva con el diagnóstico de IAM (IAMNEST = 569; IAMEST = 549). El RL se obtuvo en la primera determinación analítica. Se utilizaron modelos de regresión de Cox para determinar el grado de asociación entre el RL y la mortalidad total para ambos tipos de IAM. La mediana de seguimiento fue de 10 ± 2 meses. El RL se incluyó en ambos modelos categorizado en los siguientes puntos de corte (x 10^9 células/ml): < 10 (RL1); 10-14,9 (RL2) y ≥ 15 (RL3).

Resultados. Durante el seguimiento se registraron 105 muertes (18,5%) en pacientes con IAMNEST y 109 (19,9%) con IAMEST. Las hazard ratio ajustadas para las categorías RL2 y RL3 frente a RL1 en el grupo con IAMEST fueron: 1,61 (1,03-2,51; p = 0,036) y 2,07 (1,08-3,94; p = 0,027), y en el IAMEST: 2,22 (1,35-3,63; p = 0,002) y 2,07 (1,13-3,76; p = 0,017), respectivamente.

Conclusiones. El RL determinado en las primeras horas de un IAM demostró ser un predictor independiente de otras variables de contrastado valor pronóstico para predecir la mortalidad total a largo plazo en el IAMNEST y el IAMEST.

INTRODUCTION

In recent years, increasing evidence has become available supporting the role of inflammation in the development of atherosclerosis and the pathogenesis of coronary thrombosis.\textsuperscript{1-4} Recent studies have shown that increased levels of certain inflammatory markers in patients with acute coronary syndrome (ACS) are associated with an increased number of cardiovascular complications and a higher incidence of death, both in the short term and in the long term.\textsuperscript{5-10} However, the majority of these markers are not universally available, their cost is high, and results are not usually available immediately. Consequently, their usefulness is limited in day to day clinical practice.

Various publications have shown that increased white blood cell count (WBC) is associated with a higher incidence of cardiovascular disease and all-cause mortality in the general population.\textsuperscript{11-17} Recent studies have supported the prognostic value of the WBC as a predictor of the development of heart failure and death in both the short term and long term following ACS, particularly following acute myocardial infarction (AMI).\textsuperscript{18-27} However, less data is available in the literature concerning unselected populations in which the new definition of AMI is applied and long-term follow-up performed.\textsuperscript{28}

The aim of this study was to assess the association between WBC at admission and long-term mortality in patients with non-ST-segment elevation AMI (non-STEMI) or with ST-segment elevation AMI (STEMI).

PATIENTS AND METHODS

Study Group and Protocol

A prospective study was performed in a population of 1118 consecutive patients admitted with a diagnosis of AMI between November 1, 2000, and February 28, 2003, in the Hospital Clinic i Universitari, Valencia, Spain. Patients were stratified according to changes recorded in the ST segment of the electrocardiogram on admission: 569 non-STEMI patients and 549 STEMI patients. Therapeutic regimens were established on the basis of the stratification. The inclusion criteria used were those of the American College of Cardiology and the European Society of Cardiology.\textsuperscript{29} The criteria for STEMI were as follows: an increase in the levels of markers of myocardial necrosis (troponin I>1 ng/mL); new ST elevation from the J point in 2 or more contiguous leads with an elevation of at least 0.2 mV in leads V1, V2, and V3, or at least 0.1 mV in the remaining leads during the first 24 hours following the onset of symptoms. Patients were also included if a new ST-segment elevation in the presenting electrocardiogram was associated with a recent episode of chest pain but in whom it was not possible to obtain analyses of myocardial necrosis markers due to premature death, or if obtained, did not have values indicative of myocardial necrosis.\textsuperscript{30} The criteria for definition of non-STEMI were as follows: increased levels of markers of myocardial necrosis (as for STEMI) along with the presence of either symptoms of ischemia or alterations of the ST segment (except persistent ST-segment elevation). The treatment strategy for each type of AMI was based on established national and international guidelines.\textsuperscript{29,31} The requirement for an invasive study and revascularization was left to the judgment of the attending cardiologist. It is noteworthy that none of these patients had been transferred from other hospitals due to poor clinical progress. Patients with infectious, systemic inflammatory, or hematologic disease at admission were excluded from the study.

Variables Included in the Study

The variables analyzed in both types of AMI were obtained at admission and within the following 24 hours.

The following variables were recorded: medical history including age, sex, arterial hypertension, smoking, dyslipidemia, diabetes mellitus, personal and family history of ischemic heart disease, and percutaneous and surgical revascularization; systolic arterial pressure and Killip class determined at admission; ST-segment deviation (>1 mm in at least 2 contiguous leads) and number of leads involved; serum creatinine (mg/dL); WBC (cells/mL). In addition, maximum troponin I concentration (ng/mL) was determined in non-STEMI patients, and in STEMI patients the additional variables of heart rate, new left bundle branch block, episodes of sustained ventricular tachycardia/ventricular fibrillation in the first 24 hours, site of the AMI, thrombolysis, and electrocardiographic indicators of reperfusion (reduction in ST-segment elevation of at least 50% 90 minutes after thrombolysis) were assessed.

Definition of Events and Follow-up

An event was defined as death by any cause during a maximum follow-up period of 2 years (median follow-up period in the study population of 10±2 months). Follow-up was undertaken in the outpatients...
clinic of our hospital or through telephone contact with a member of the medical staff.

Statistical Analysis

The WBC determined at admission was assigned to 1 of 3 categories (×10^3 cells/mL): WBC1<10, WBC2=10 to 14.9, WBC3≥15. The cutoff points were selected according to previous studies. Quantitative variables were expressed as means (SD) and comparisons were made between the 3 WBC categories by analysis of variance. Data that did not display a normal distribution were expressed as medians (interquartile range) and were compared using the Kruskal-Wallis test. Qualitative variables were expressed as percentages and compared using the χ² test. Cumulative mortality for each WBC category was presented using Kaplan-Meier curves and differences between the categories were assessed using the Peto-Peto-Prentice test. The Cox proportional hazard regression model was used for multivariate analysis. Multivariate models were constructed using systematically obtained data collected from all patients within the first 24 hours of admission, independently of the type of AMI. Variables described in the literature as having recognized prognostic value were included irrespective of their level of statistical significance; variables not described in the literature as having prognostic value were only included if P<.20 in the bivariate analysis. Once the initial models were established, they were simplified by step-down variable selection. The assumption of proportionality of the risk was evaluated via analysis of the Schoenfeld residuals and the functional form of the quantitative variables (log-linear relationship) was determined using fractional polynomials. The discriminatory power of the adjusted models was evaluated using Harrell’s c index for censored data. The estimated coefficients were expressed as hazard ratios with the respective 95% confidence intervals. In all cases, P<.05 was considered statistically significant. Statistical analyses were performed using the STATA statistical software package version 8.2.

RESULTS

Baseline Characteristics of the Study Group

The WBC of the study population had a range of 3.1-35×10^3 cells/mL. The median of the population was 9.8×10^3 cells/mL with an interquartile range of 7.8-12.5×10^3 cells/mL. The baseline clinical and demographic characteristics were stratified separately for each type of AMI according to the previously established WBC categories (Tables 1 and 2).

Non-STEMI

The distribution of the non-STEMI population according to WBC category was as follows: 351 patients

*PTCA indicates percutaneous transluminal coronary angioplasty; non-STEMI, non-ST-segment elevation myocardial infarction; SAP, systolic arterial pressure.

†P value for the linear tendency.
(62.9%) were in category WBC1, 176 (30.9%) in WBC2, and 35 (6.2%) in WBC3. The mean age of the patients was 70 (12.1) years and 65% were men. The proportion of patients with diabetes mellitus, Killip class >2, and troponin I levels >1 ng/mL displayed a monotonic increase from WBC1 to WBC3, while the percentage of men was inversely proportional to the WBC. No other significant differences were observed for other study variables (Table 1).

**STEMI**

The distribution of the STEMI population according to WBC category was as follows: 228 patients (41.5%) were in category WBC1, 239 (43.5%) in WBC2, and 82 (14.9%) in WBC3. The mean age of the patients was 65±13 years and 72.9% were men. In this type of AMI, the proportion of active smokers, Killip class >2 at admission, heart rate >100 beats per minute, systolic arterial pressure <100 mm Hg, an episode of sustained ventricular tachycardia/ventricular fibrillation in the first 24 hours, the number of leads with ST-segment elevation, and the appearance of new Q waves displayed a proportional increase from WBC1 to WBC3, while the relationship was inversely proportional for the proportion of patients above 65 years, those with a history of ischemic heart disease, and in patients who met electrocardiographic criteria for reperfusion (Table 2).

**White Blood Cell Count and Overall Mortality**

A total of 214 deaths (19.1% of the total population) were registered during follow-up: 105 (18.5%) in non-STEMI patients and 109 (19.9%) in STEMI patients. Bivariate analysis revealed that short-term (Tables 1 and 2) and long-term mortality increased proportionally between the WBC categories for both types of AMI (Tables 3 and 4). The Kaplan-Meier curves revealed separation of the groups according to WBC category from the earliest point in the follow-up, particularly in the STEMI patients (Figure 1B), and that these differences persist and even increase during follow-up for both types of AMI (Figure 1A and B).

**Non-STEMI**

The final multivariate analysis of this group included only covariables obtained in the first 24 hours following the onset of symptoms (Figure 2A). The long-term risk of death compared with the WBC1 category was 1.61 (1.03–2.51; \( P = .036 \)) and 2.07 (1.08–3.94; \( P = .027 \)) times higher in categories WBC2 and WBC3, respectively (Figure 2A). Analysis of the functional
MI patients, independently of other variables of known prognostic value.

The literature contains an increasing amount of information that supports the prognostic value of inflammatory markers across a wide clinical spectrum of atherosclerotic disease, from their role in plaque pathogenesis to their usefulness in quantifying the inflammatory response during AMI.1-10

A number of epidemiological studies have shown that the baseline WBC is associated with an increased incidence of ischemic heart disease and mortality in the general population1-17 and there is current scientific interest in the potential prognostic value of the WBC determined during the acute phase of AMI to predict subsequent complications. Thus, recent studies have shown an association between an increased WBC and a higher incidence of complications following AMI, in particular, heart failure and short- and long-term mortality.18-28

A number of mechanisms have been proposed to explain the observed relationship between WBC and AMI outcomes. These include the release of inflammatory cytokines and chemokines from activated leukocytes, which can promote vascular inflammation and injury, leading to the formation of atherosclerotic plaques and the development of AMI. Additionally, leukocytes may contribute to the process of platelet aggregation and fibrin formation, which are important in the pathogenesis of AMI.29-31

**DISCUSSION**

This study shows that WBC determined in the first few hours of AMI is a predictor of long-term mortality in the early risk stratification of STEMI and non-STEMI patients, independently of other variables of known prognostic value.

**STEMI**

The final multivariate model for the whole group showed that the adjusted risk of death compared with category WBC1 was 2.22 (1.35-3.63; P = .002) and 2.07 (1.13-3.76; P = .017) times higher in categories WBC2 and WBC3, respectively (Figure 2B). Analysis of the functional form of the variable revealed that the risk of death attributable to WBC begins at just above 10×10⁹ cells/mL; however, visual examination of the curve (Figure 3B) revealed a slight plateau beyond this point. The c index in this case was 0.85.

plain this association: resistance to thrombolytic therapy due to alterations in the microcirculation, hypercoagulable state, a no-reflow phenomenon caused by leukocytes, indirect cardiotoxicity mediated by proinflammatory cytokines, promoters of ischemia-reperfusion injury, and expansion of the AMI. Regarding
this final point, it is important to bear in mind that the leukocyte response that occurs following AMI is a central part of the inflammatory reparative response that is initiated to replace the necrotic tissue with scar tissue. This may suggest that the greater the amount of necrosis, the larger the leukocyte response, an assertion based on experimental studies that show a direct relationship between the extent of necrosis and the level of both the local and the systemic leukocyte response. In addition, depletion of neutrophils in animal models in which coronary occlusion is performed leads to a significant reduction in the size of the infarct and the extent of reperfusion injury. In clinical settings, the extent of AMI is estimated using indirect parameters. Thus, various studies have related the WBC to variables associated with the size of the AMI: the development of heart failure, and significant correlations with the peak level of isoenzyme MB of creatine kinase (CK-MB), or with left ventricular ejection fraction. In our sample, the proportion of the population with a Killip class >2 or a systolic arterial pressure <100 mm Hg showed a monotonic increase from one WBC category to the next in patients with either type of AMI. This was particularly apparent in the STEMI group, an observation that indirectly supports the association between WBC and the extent of AMI. This was particularly apparent in the STEMI group, with a Killip class >2, systolic arterial pressure <100 mm Hg, and serum creatinine level. STEMI indicates ST-segment elevation myocardial infarction; non-STEMI, non-ST-segment elevation myocardial infarction.

Figure 3. Risk profile for long-term mortality attributable to white blood cell count in non-STEMI (A) and STEMI (B). Profile for non-STEMI adjusted for age, sex, diabetes mellitus, maximum concentration of troponin I, Killip class >2, and serum creatinine level. Profile for STEMI adjusted for age, sex, complicated left bundle branch block, electrocardiographic criteria for reperfusion, Killip class >2, systolic arterial pressure <100 mm Hg, and serum creatinine level. STEMI indicates ST-segment elevation myocardial infarction; non-STEMI, non-ST-segment elevation myocardial infarction.

The following represent inherent limitations in the

Limitations

The following represent inherent limitations in the
study design: a) those limitations that are applicable to any observational study due to the difficulty of inclu-
ding variables with unknown prognostic value or that
were not collected in our study; b) in the absence of a
differential WBC at admission, we were unable to de-
termine whether the prognostic value of the WBC was
due to a specific component (e.g., neutrophils); c) the
inclusion of only variables that can be collected during
the first 24 hours following hospital admission preven-
ted adjustment for other variables with known prog-
nostic value that are usually assessed over the course
of hospital stay, such as left ventricular ejection frac-
tion.

CONCLUSIONS

The WBC determined at hospital admission in STE-
MI and non-STEMI patients was associated with long-
term mortality, independently of other variables with
known prognostic value. Consequently, we consider
WBC to be a useful and widely available biological
tool with which to identify patients at increased risk of
death.
